A Case of Aspiration Pneumonia Caused by Gastroesophageal Reflux Disease in A Percutaneous Endoscopic Gastrostomy Patient

Shinji Takahashi 1 and Naoyuki Kobayashi 2

The patient was an eighty-year-old female. She underwent a Percutaneous Endoscopic Gastrostomy (PEG) in 1999 and has taken her daily nutrition through this until April 2007. She experienced a fever of 39°C in May 2007 and was admitted to this hospital for further examination. Computed Tomography (CT) taken at the time of her admission showed pneumonia in the right lung. Furthermore, there was a moderate amount of fluid collected in the esophagus and esophageal dilatation was also observed. The patient eventually died of recurrent aspiration pneumonia. When patients are observed to have fluid collected in the esophagus and esophageal dilatation on CT, then the existence of gastroesophageal reflux disease must be suspected and a careful nutritional strategy must be established in a timely manner. (Kitakanto Med J 2008 : 58 : 315~316)

Key Words : aspiration pneumonia, gastroesophageal reflux disease, percutaneous endoscopic gastrostomy

Introduction

A Percutaneous Endoscopic Gastrostomy (PEG) is widely performed in many medical facilities and gives great benefits for the patients who has difficulties in obtaining sufficient nutrition such as cerebrovascular disorders and neuromuscular diseases which require a long term nutrition supply. Most of these patients are also bedridden. However, gastroesophageal reflux disease remains a problem in such cases because it can cause aspiration pneumonia, which can be fatal in such patients because it is often difficult for them to drain their sputum. This report describes a case of severe aspiration pneumonia due to gastroesophageal reflux disease which occurred after feeding through a PEG.

Case report

The patient was an eighty-year-old female. She underwent a PEG in 1999, and has since received her nutrition through this until April 2007. During this period, she sometimes suffered from aspiration pneumonia but these symptoms were not critical. She experienced a fever of 39°C in May 2007 and was therefore admitted to this hospital for further examination. Computed Tomography (CT) taken at the time of her admission showed pneumonia in the right lung (Fig. 1a). Furthermore, there was also a moderate amount of fluid collected in the esophagus and esophageal dilatation was observed (Fig. 1b). As a result, antibiotics were administered (3 g/day SBT/CPZ). The pneumonia gradually improved and feeding was resumed through the PEG three times per day for a few days. Initially, she showed no complications, therefore daily feeding was continued through the PEG. However, she thereafter showed reflux from

Fig. 1a Computed Tomography taken at the time of her admission showed pneumonia in the right lung.

the stomach to the esophagus, and she instantly demonstrated symptoms of aspiration pneumonia again. This disease proved to be extremely resistant to therapy. Sputum cultures showed Pseudomonas aeruginosa and MRSA, as a result, 2 g/day CAZ and 1 g/day VCM were administered. Furthermore, the gastric juice was passively drained through the PEG to prevent any further gastroesophageal reflux. Despite these measures, fluid collection in the esophagus still appeared on the CT findings (Fig. 2). The patient eventually died of recurrent aspiration pneumonia in June 2007.

**Discussion**

PEG is a very useful procedure when patients have difficulty obtaining sufficient nutrition. Feeding through the gastrointestinal tract is better than total parenteral nutrition (TPN) from a nutritional point of view. It is well known that the rate of sepsis is significantly lower and the morbidity rate in high risk surgical patients is better when patients use PEG in comparison to TPN. Despite these benefits from PEG, we often experience aspiration pneumonia in PEG patients especially in the elderly. The cause of aspiration in a PEG patient is often due to gastroesophageal reflux or aspiration of the patient’s own oropharyngeal secretions due to the underlying neurologic deficit or cancer. Furthermore, it is well-known that the prevalence of hiatus hernia and severe gastroesophageal reflux is higher in the elderly. Increasing age was associated with decreasing abdominal lower esophageal sphincter length and increasing prevalence of ineffective esophageal motility. As a result, even if patients do not manifest any symptoms of gastroesophageal reflux or aspiration during early period after a PEG was performed, they can suffer from them as they get older, as observed in our case. However, it is difficult to predict the occurrence of gastroesophageal reflux or aspiration. Thoracic CT findings, such as fluid collection in the esophagus or dilation of esophagus can therefore be a useful marker of gastroesophageal reflux. When patients are observed with such abnormalities on the CT, we should use a high-viscosity liquid meal to decrease the occurrence of gastroesophageal reflux. If this is not effective, then we should perform TPN.
